Directory-Based Cache Coherence in Large-Scale Multiprocessors

David Chaiken, Craig Fields, Kiyoshi Kurihara, and Anant Agarwal
Massachusetts Institute of Technology

In a shared-memory multiprocessor, the memory system provides access to the data to be processed and mechanisms for interprocess communication. The bandwidth of the memory system limits the speed of computation in current high-performance multiprocessors due to the uneven growth of processor and memory speeds. Caches are fast local memories that moderate a multiprocessor's memory-bandwidth demands by holding copies of recently used data, and provide a low-latency access path to the processor. Because of locality in the memory access patterns of multiprocessors, the cache satisfies a large fraction of the processor accesses, thereby reducing both the average memory latency and the communication bandwidth requirements imposed on the system’s interconnection network.

Caches in a multiprocessor environment introduce the cache-coherence problem. When multiple processors maintain locally cached copies of a unique shared memory location, any local modification of the location can result in a globally inconsistent view of memory. Cache-coherence schemes prevent this problem by maintaining a uniform state for each cached block of data.

Several of today's commercially available multiprocessors use bus-based memory systems. A bus is a convenient device for ensuring cache coherence because it allows all processors in the system to observe ongoing memory transactions. If a bus transaction threatens the consistent state of a locally cached object, the cache controller can take such appropriate action as invalidating the local copy. Protocols that use this mechanism to ensure coherence are called snoopy protocols because each cache snoops on the transactions of other caches.

Unfortunately, buses simply don’t have the bandwidth to support a large number of processors. Bus cycle times are restricted by signal transmission times in multidrop environments and must be long enough to allow the bus to “ring out,” typically a few signal propagation delays over the length of the bus. As processor speeds increase, the relative disparity between bus and processor clocks will simply become more evident.

Consequently, scalable multiprocessor systems interconnect processors using short point-to-point wires in direct or multistage networks. Communication along impedance-matched transmission line channels can occur at high speeds, providing communication bandwidth that
scales with the number of processors. Unlike buses, the bandwidth of these net-
works increases as more processors are added to the system. Unfortunately, such
networks don’t have a convenient snooping mechanism and don’t provide an effi-
cient broadcast capability. In the absence of a systemwide broadcast mecha-
nism, the cache-coherence problem can be solved with interconnec-
tion networks using some variant of direc-
tory schemes. This article reviews and
analyzes this class of cache-coherence
protocols. We use a hybrid of trace-driven
simulation and analytical methods to
evaluate the performance of these schemes for
several parallel applications.

The research presented in this article is
part of our effort to build a high-perfor-
ance large-scale multiprocessor. To that
eend, we are studying entire multiprocessor
systems, including parallel algorithms,
compilers, runtime systems, processors,
caches, shared memory, and interconnec-
tion networks. We find that the best solu-
tions to the cache-coherence problem re-
sult from a synergy between a multiproces-
sor’s software and hardware components.

**Classification of directory schemes**

A cache-coherence protocol consists of
the set of possible states in the local caches,
the states in the shared memory, and the
state transitions caused by the messages trans-
ported through the interconnection network
to keep memory coherent. To simplify the
protocol and the analysis, our data
block size is the same for coherence
and cache fetch.

A cache-coherence protocol that does not use broadcasts must store the locations of
all cached copies of each block of shared
data. This list of cached locations, whether
centralized or distributed, is called a direct-
ory. A directory entry for each block of
data contains a number of pointers to
specify the locations of copies of the block.
Each directory entry also contains a dirty bit
that indicates whether or not a unique cache
has permission to write the associated
block of data. The different flavors of directory proto-
col fall under three primary categories:
full-map directories, limited directories,
and chained directories. Full-map directo-
ries store enough state associated with
each block in global memory so that every
cache in the system can simultaneously
store a copy of any block of data. That is,
each directory entry contains \( N \) pointers,
where \( N \) is the number of processors in the
system. Such directories can be optimized
to use a single bit pointer. Limited directo-
ries differ from full-map directories in
that they have a fixed number of pointers
per entry, regardless of the number of
processors in the system. Chained directo-
ries emulate the full-map schemes by
distributing the directory among the

To analyze these directory schemes, we
chose at least one protocol from each catego-
ry. In each case, we tried to pick the
protocol that was the least complex to
implement in terms of the required hard-
ware overhead. Our method for simplifying
an approach was to minimize the number of
cache states, memory states, and types of
protocol messages. All of our protocols
guarantee sequential consistency, which
Lamport defined as ensuring the correct exec-
tion of multiprocessor programs.

**Full-map directories.** The full-map
protocol uses directory entries with one bit
per processor and a dirty bit. Each bit
represents the status of the block in the
corresponding processor’s cache (present
or absent). If the dirty bit is set, then one
and only one processor’s bit is set, and that
processor has permission to write into the
block. A cache maintains two bits of state
per block. One bit indicates whether a
block is valid; the other bit indicates
whether a valid block may be written. The
cache-coherence protocol must keep the
state bits in the memory directory and those
in the caches consistent.

Figure 1a illustrates three different
states of a full-map directory. In the first
state, location \( X \) is missing in all of the
caches in the system. The second stage
results from three caches (C1, C2, and C3)
requesting copies of location \( X \). Three
pointers (processor bits) are set in the
entry to indicate the caches that have copies
of the block. In the first two states, the
dirty bit — on the left side of the directory
entry — is set to clean \( C \), indicating that
no processor has permission to write to the
block of data. The third state results from
cache C3 requesting write permission for
the block. In this final state, the dirty bit
is set to dirty \( D \), and there is a single pointer
to the block of data in cache C3.

It is worth examining the transition from
the second state to the third state in more
detail. Once processor P3 issues the write
to cache C3, the following events tran-
spire:

1. Cache C3 detects that the block
containing location \( X \) is valid but that the
processor does not have permission to
write to the block, indicated by the block’s
write-permission bit in the cache.

2. Cache C3 issues a write request to
the memory module containing location \( X \)
and stalls processor P3.

3. The memory module issues invalid-
ate requests to caches C1 and C2.

4. Cache C1 and cache C2 receive the
invalidate requests, set the appropriate bit
to indicate that the block containing location
\( X \) is invalid, and send acknowledg-
ments back to the memory module.

5. The memory module receives the
acknowledgment, sets the dirty bit, clears
the pointers to caches C1 and C2, and sends
write permission to cache C3.

6. Cache C3 receives the write
permission message, updates the state in the
cache, and reactivates processor P3.

Note that the memory module waits to
receive the acknowledgments before al-
lowing processor P3 to complete its write
transaction. By waiting for acknowledg-
ments, the protocol guarantees that the
memory system ensures sequential consis-
tency.

The full-map protocol provides a useful
upper bound for the performance of cen-
tralized directory-based cache coherence.
However, it is not scalable with respect to
memory overhead. Assume that the
amount of distributed shared memory in-
creases linearly with the number of
processors \( N \). Because the size of the direc-
tory entry associated with each block of
memory is proportional to the number of
processors in the memory consumed by the
directory is proportional to the size of
memory (\( \Theta(N) \)) multiplied by the size of
the directory entry (\( \Theta(1) \)). Thus, the total
memory overhead scales as the square of
the number of processors (\( \Theta(N^2) \)).

**Limited directories.** Limited directory
protocols are designed to solve the directory
size problem. Restricting the number of
simultaneously cached copies of any
particular block of data limits the growth
of the directory to a constant factor. For our
analysis, we selected the limited directory
protocol proposed in Agarwal et al. A
directory protocol can be classified as
\( \text{Dir}_i \) using the notation from Agarwal et
al. The symbol \( i \) stands for the number of
pointers, and \( X \) is NB for a scheme with no
broadcast and B for one with broadcast. A
full-map scheme without broadcast is rep-
resented as \( \text{Dir}_{NB} \). A limited directory
protocol that uses i/C pointers is denoted DirNB. The limited directory protocol is similar to the full-map directory, except in the case when more than i caches request read copies of a particular block of data.

Figure 1b shows the situation when three caches request read copies in a memory system with a DirNB protocol. In this case, we can view the two-pointer directory as a two-way set-associative cache of pointers to shared copies. When cache C3 requests a copy of location X, the memory module must invalidate the copy in either cache C1 or cache C2. This process of pointer replacement is sometimes called eviction. Since the directory acts as a set-associative cache, it must have a pointer replacement policy. Our protocol uses an easily implemented pseudorandom eviction policy that requires no extra memory overhead. In Figure 1b, the pointer to cache C3 replaces the pointer to cache C2.

Why might limited directories succeed? If the multiprocessor exhibits processor locality in the sense that in any given interval of time only a small subset of all the processors access a given memory word, then a limited directory is sufficient to capture this small "worker-set" of processors.

Directory pointers in a DirNB protocol encode binary processor identifiers, so each pointer requires $\log_2 N$ bits of memory, where $N$ is the number of processors in the system. Given the same assumptions as for the full-map protocol, the memory overhead of limited directory schemes grows as $\Theta(N \log N)$. These protocols are considered scalable with respect to memory overhead because the resources required to implement them grow approximately linearly with the number of processors in the system.

DirB protocols allow more than i copies of each block of data to exist, but they resort to a broadcast mechanism when more than i cached copies of a block need to be invalidated. However, interconnection networks with point-to-point wires do not provide an efficient systemwide broadcast capability. In such networks, it is also difficult to determine the completion of a broadcast to ensure sequential consistency. While it is possible to limit some DirB broadcasts to a subset of the system (see Agarwal et al.), we restrict our evaluation of limited directories to the DirNB protocols.

Chained directories. Chained directories, the third option for cache-coherence schemes that do not utilize a broadcast mechanism, realize the scalability of limited directories without restricting the number of shared copies of data blocks. This type of cache-coherence scheme is called a chained scheme because it keeps track of shared copies of data by maintaining a chain of directory pointers. We investigated two chained directory schemes.

The simpler of the two schemes implements a singly linked chain, which is best described by example (see Figure 1c). Suppose there are no shared copies of location X. If processor P1 reads location X, the memory sends a copy to cache C1, along with a chain termination (CT) pointer. The memory also keeps a pointer to cache C1. Subsequently, when processor P2 reads location X, the memory sends a copy to cache C2, along with the pointer to cache C1. The memory then keeps a pointer to cache C2. By repeating this step, all of the caches can cache a copy of location X. If processor P3 writes to location X, it is necessary to send a data invalidation message down the chain. To ensure sequential consistency, the memory module denies processor P3 write permission until the processor with the chain termination pointer acknowledges the invalidation of the chain. Perhaps this scheme should be called a gossip protocol (as opposed to a snoopy protocol) because information is...
passed from individual to individual, rather than being spread by covert observation.

The possibility of cache-block replacement complicates chained directory protocols. Suppose that cache \( C_x \) through cache \( C_y \) all have copies of location \( X \) and that location \( X \) and location \( Y \) map to the same (direct-mapped) cache line. If processor \( P \) reads location \( Y \), it must first evict location \( X \) from its cache. In this situation, two possibilities exist:

1. Send a message down the chain to cache \( C_x \), with a pointer to cache \( C_y \), and splice \( C_y \) out of the chain, or
2. Evict location \( X \) in cache \( C_{n1} \) through cache \( C_y \).

For our evaluation, we chose the second scheme because it can be implemented by a less complex protocol than the first. In either case, sequential consistency is maintained by locking the memory location while invalidations are in progress.

Another solution to the replacement problem is to use a doubly linked chain. This scheme maintains forward and backward chain pointers for each cached copy so that the protocol does not have to traverse the chain when there is a cache replacement. The doubly linked directory optimizes the replacement condition at the cost of a larger average message block size (due to the transmission of extra directory pointers), twice the pointer memory in the caches, and a more complex coherence protocol.

Although the chained protocols are more complex than the limited directory protocols, they are still scalable in terms of the amount of memory used for the directory. The pointer sizes grow as the logarithm of the number of processors, and the number of pointers per cache or memory block is independent of the number of processors.

Caching only private data. Up to this point, we have assumed that caches are allowed to store local copies of shared variables, thus leading to the cache-consistency problem. An alternative shared memory method avoids the cache-coherence problem by disallowing caching of shared data. In our analysis, we designate this scheme by saying it only caches private data. This scheme caches private data, shared data that is read-only, and instructions, while references to modifiable shared data bypass the cache. In practice, shared variables must be statically identified to use this scheme.

Methodology

What is a good performance metric for comparing the various cache-coherence schemes? To evaluate the performance of the memory system, which includes the cache, the memory, and the interconnection network, we determine the contribution of the memory system to the time needed to run a program on the system. Our analysis computes the processor utilization, or the fraction of time that each processor does useful work. One minus the utilization yields the fraction of processor cycles wasted due to memory system delays. The actual system speedup equals the number of processors multiplied by the processor utilization. This metric has been used in other studies of multiprocessor cache and network performance.

In a multiprocessor, processor utilization (and therefore system speedup) is affected by the frequency of memory references and the latency of the memory system. The latency \( T \) of a message through the interconnection network depends on several factors, including the network topology and speed, the number of processors in the system, the frequency and size of the messages, and the memory access latency. The cache-coherence protocol determines the request rate, message size, and memory latency. To compute processor utilization, we need to use detailed models of cache-coherence protocols and interconnection networks.

Figure 2 shows an overview of our analysis process. Multiprocessor address traces generated using three tracing methods at Stanford University, IBM, and MIT...
are run on a cache and directory simulator that counts the occurrences of different types of protocol transactions. A cost is assigned to each of these transaction types to compute the average processor request rate, the average network message block size, and the average memory latency per transaction. From these parameters, a model of a packet-switched, pipelined, multistage interconnection network calculates the average processor utilization.

Getting multiprocessor address trace data. The address traces represent a wide range of parallel algorithms written in three different programming languages. The programs traced at Stanford were written in C, at IBM, in Fortran; and at MIT, in Multiplex, a variant of Multilisp. The implementation of the trace collector differs for each of the programming environments. Each tracing system can theoretically obtain address traces for an arbitrary number of processors, enabling a study of the behavior of cache coherent machines much larger than any built to date. Table 1 summarizes general characteristics of the traces. We will compare the relative performance of the various coherence schemes individually for each application.

The SA-TSP, MP3D, P-Thor, and LocasRoute traces were gathered via the Trap-Bit method using 16 processors. SA-TSP uses simulated annealing to solve the traveling salesman problem. MP3D is a 3D particle simulator for randomized flow. P-Thor is a parallel logic simulator. LocasRoute is a global router for VLSI standard cells. Weber and Gupta provide a detailed description of the applications.

Trap-bit (T-bit) tracing for multiprocessors is an extension of single-processor trap-bit tracing. In the single processor implementation, the processor traps after each instruction if the trap bit is set, allowing interpretation of the trapped instruction and emission of the corresponding memory addresses. Multiprocessor T-bit tracing extends this method by scheduling a new process on every trapped instruction. Once a process undergoes a trap, the trace mechanism performs several tasks. It records the corresponding memory addresses, saves the processor state of the trapped process, and schedules another process from its list of processes, typically in a round-robin fashion.

The Weather, Simple, and fast Fourier transform traces were derived using the postmortem scheduling method at IBM. The Weather application partitions the atmosphere around the globe into a three-dimensional grid and uses finite-difference methods to solve a set of partial differential equations describing the state of the system. Simple models the behavior of fluids and employs finite difference methods to solve equations describing hydrodynamic behavior. FFT is a radix-2 fast Fourier transform.

Postmortem scheduling is a technique that generates a parallel trace from a uni-processor execution trace of a parallel application. The uniprocessor trace is a task trace with embedded synchronization information that can be scheduled, after execution (postmortem), into a parallel trace that obeys the synchronization constraints. This type of trace generation uses only one processor to produce the trace and to perform the postmortem scheduling. So, the number of processors is limited only by the application's synchronization constraints and by the number of parallel tasks in the single processor trace.

The Speech trace was generated by a compiler-aided tracing scheme. The application comprises the lexical decoding stage of a phonetically based spoken language understanding system developed by the MIT Spoken Language Systems Group. The Speech application uses a dictionary of about 300 words represented by a 3,500-node directed graph. The input to the lexical decoder is another directed graph representing possible sequences of phonemes in the given utterance. The application uses a modified Viterbi search algorithm to find the best match between paths through the two graphs.

In a compiler-based tracing scheme, code inserted into the instruction stream of a program at compile time records the addresses of memory references as a side effect of normal execution. Our compiler-aided multiprocessor trace implementation is T-Mul-T, a modification of the Multiplemmum environment.

It does produce accurate counts of each type of protocol transaction over the length of a correct execution of a parallel program.

However, since we assume that all side effects of any transaction occur simultaneously, we do not model the difference between sequential and concurrent operations. This inaccuracy particularly affects the analysis of chained directory schemes. Specifically, when a shared write is performed in a system that uses a chained directory scheme, the copies of the written location must be invalidated in sequence, while a centralized directory scheme may send the invalidations in parallel and keep track of the number of outstanding acknowledgments. Thus, the minimum latency for shared writes to clean cache blocks is greater for the distributed schemes than for the centralized schemes.

Analyzing the trade-offs between centralized and distributed schemes requires a much more detailed simulation. While it is possible to accurately model the memory system on a cycle-by-cycle basis, such a simulation requires much higher overhead than our simulations in terms of both programming time and simulation runtime. Our MIT research group is running experiments on a simulator for an entire multiprocessor system. Simulations of the entire system run approximately 100 times slower than the trace-driven simulations used for this article. Variants of coherence schemes are harder to implement in the detailed simulator than in the trace-driven environment. To investigate a wide range of applications and cache-coherence protocols, we avoided the high overhead of such detailed simulations by performing trace-driven simulations.

In a trace-driven simulation, a memory transaction consists of a processor-to-memory reference and its effect on the state of the memory system. Any transaction that causes a message to be sent over the network contributes to the average request rate, average message size, and average memory latency. Each type of transaction is assigned a cost in terms of the number of messages that must be sent over the network (including both the requests and the responses), the latency encountered at the memory modules, and the total number of words (including routing information) transported through the network. Given a trace and a particular cache-coherence protocol, the cache and directory simulator determines the percentage of each transaction type in the trace. The percentage of the transaction type, multiplied by its cost, gives the contribution of the transaction to each of the three parameters listed above.

In addition to the cache-coherence strategy, other parameters affect the performance of the memory system. We chose values for these parameters (listed in Table 2) based on the technology used for contemporary multiprocessors. Although we chose a 256 kilobyte cache, the results of our analysis do not differ substantially for cache sizes from 256 kilobytes down to 16 kilobytes because the working sets for the applications are small when partitioned over a large number of processors. The effect of other parameters, including the cache-block size, has been explored in several studies (see Eggers and Katz' and references therein).

The interconnection network model. The directory schemes that we analyze transmit messages over an interconnection network to maintain cache coherence. They distribute shared memory and associated directories over the processing nodes. Our analysis uses a packet-switched, buffered, multistage interconnection network that belongs to the general class of Omega networks. The network switches are pipeline so that a message header can leave a switch even while the rest of the message is still being serviced. A protocol message travels through a network switch stages to the destination node and takes $M$ cycles for the memory access. The network is buffered and guarantees sequenced delivery of messages between any two nodes on the network.

Computation of the processor utilization is based on the analysis method that Patil used. The network model yields the average latency $T$ of a protocol message through the network with $n$ stages, $k \times k$ size switches, and average memory delay $M$. We derive processor utilization $U$ from a set of three equations:

$$U = \frac{1}{1 + mT}$$

$$\rho = U mB$$

$$T = n + B + M - 1 + \left( \frac{DB(1 - \rho)}{2(1 - \rho)} \right) n$$

where $m$ is the probability a message is generated on a given processor cycle, with corresponding network latency $T$. The channel utilization $(\rho)$ is the product of the effective network request rate $(U m)$ and the average message size $B$. The latency equation uses the packet-switched network model by Kruskal and Snir. The first term in the equation $(n + B + M - 1)$ gives the latency through an unloaded network. The second term gives the increase in latency due to network contention, which is the product of the contention delay through one switch and the number of stages. We verified the model in the context of our research by comparing its predictions to the performance of a packet-switched network simulator that transmitted messages generated by a Poisson process.

Table 2 shows the default network parameters we used in our analysis. While this article presents results for a packet-switched multistage network, it is possible to derive results for other types of net-
works by varying the network model used in the final stage of the analysis. In fact, we repeated our analysis for the direct, two-dimensional mesh network that we plan to use in our own machine. With the direct network model, the cache-coherence schemes showed the same relative behavior as they did with the network model described above. The ability to use the results from one set of directory simulations to derive statistics for a range of network or bus types displays the power of this modeling method.

Analysis of directory schemes

The graphs presented below plot various combinations of applications and cache-coherence schemes on the vertical axis and processor utilization on the horizontal axis. Since the data reference characteristics vary significantly between applications and trace gathering methods, we do not average results from the different traces. The results presented here concentrate on the Weather, Speech, and P-Thor applications. We discuss other applications when they exhibit significantly different behavior.

Are caches useful for shared data? Figure 3 shows the processor utilizations realized for the Weather, Speech, and P-Thor applications using each of the coherence schemes we evaluated. The long bar at the bottom of each graph gives the value for “no cache coherence.” This number is derived by considering all addresses in each trace to be not shared. Processor utilization with no cache coherence gives, in a sense, the effect of the native hit/miss rate for the application. The number is artificial because it does not represent the behavior of a correctly operating system. However, the number does give an upper bound on the performance of any coherence scheme and allows us to focus on the component of processor utilization lost due to sharing between processors.

To assess the potential of shared data caching schemes in general, we compare the optimal (full-map) directory scheme to the scheme that caches only private data. For most applications (including the ones shown in Figure 3), the full-map directory yields significantly better processor utilization than the scheme that caches only private data. Generally good performance of the full-map scheme in 16 and 64 processor machines implies that caches are useful for shared data, even when applications are not written or compiled specially for a system with directory-based cache coherence.

However, for two traces (Simple and MP3D), processor utilization for a full-map directory is worse than the utilization for the private data-cache scheme. Examining the network model shows the reason it is possible for private data caches to perform better than full-map directories: Even though the private cache scheme has a higher network message rate, it uses smaller message block sizes. In the model, network latency is proportional to the square of the message block size but is linearly dependent on the message rate.

The fact that for Simple and MP3D the private data-cache scheme performs better than the full-map directory scheme indicates that the average time between writes by different processors to each shared location is low. For these traces, the full-map directory scheme does not perform significantly better than the limited directory schemes.

Limited directory performance. How well do limited directories perform compared to the full-map directory scheme? The answer depends on the amount of shared data, the number of processors that access each shared data location, and the method of synchronization. The P-Thor application was written to minimize communication between processors by reducing the number of synchronization points and the number of processors that read each shared location. It is not surprising that all of the directory schemes perform well for this application.

On the other hand, four traces show significantly worse processor utilization for limited directories than for a full-map directory due to naive synchronization techniques (Weather, Simple, and SATSP) or widespread sharing of a large read-only data structure (Speech).

Chained directory performance. When applications use data structures that are widely shared and accessed frequently, a limited directory performs significantly

June 1990
worse than a full-map directory. However, Figure 3 shows that both singly and doubly linked directories perform almost as well as the full-map directory protocols. While the doubly linked scheme always performs slightly better than the singly linked scheme, the small increase in performance may not justify the additional resources needed for the doubly linked scheme. The difference between the schemes is small because the number of replacements as a percentage of total memory accesses is very small, even though we simulated direct-mapped caches.

In general, chained directory schemes yield higher utilization than limited directory protocols. However, chained directory protocols are more complex and have higher write latency than limited directory protocols. We are still investigating the ramifications of this trade-off.

Improving the performance of directories

The results presented above show that limited directory schemes suffer from data types that are both widely shared and frequently referenced. We use the Weather and Speech applications as case studies to demonstrate two methods for ameliorating the effects of this type of data. These methods are examples of system-level optimizations because they involve contributions from several components of a multiprocessor system. In addition to improving the performance of limited directory schemes, the methods also enhance the performance of the other coherence schemes.

The Weather application uses barriers as the primary method of synchronization. In the straightforward implementation of barriers, each processor increments a barrier variable and then spin-locks on a barrier flag. The last processor to reach the synchronization point increments the barrier variable to its final value and writes the barrier flag, thereby releasing the spinning processors. The memory accesses from many processors spin-locked on a single location cause pointer thrashing (repeated evictions) in the limited directory.

A software solution, called a combining tree, can alleviate this problem in directories. Instead of implementing barrier synchronizations with a single barrier variable and barrier flag, a balanced tree structure of nodes can be used for each. To demonstrate the benefits of this barrier implementation, we modified the postmortem scheduler to implement combining tree synchronization. The resulting trace was virtually identical to the original trace, except with respect to the distribution of synchronization address accesses. In the original trace, all of the synchronization addresses were accessed by all of the processors. In the combining-tree trace, almost all of the synchronization addresses were accessed primarily by one processor, with just one access by one other processor.

The top graph in Figure 4 shows that the combining tree dramatically improves the performance of the limited directory schemes. The darker colored bars show the processor utilization of the application with linear barrier synchronization, and the lighter bars show the enhanced utilization when using the combining-tree structure. The two- and four-pointer directories yield nearly the same processor utilization as the full-map scheme. The one-pointer directory suffers from sharing of other data between processors. However, this data sharing must exist only between processor pairs, because it does not affect the two-pointer directory. Thus, combining tree structures and limited directory schemes provide an efficient implementation of barrier synchronization.

The Speech application provides an example of both a different programming model and a different type of widely shared data. There are two primary data structures in the Speech application: an utterance (the sentence to be identified) and a dictionary (the algorithm’s vocabulary). For the duration of the application, these data structures are only read, but they are shared by all the processors in the system. This type
This article has shown that, by using system-level optimizations, it is possible to build large-scale cache-coherent multiprocessors. Using processor utilization as a metric, we evaluated the performance of several cache-coherence protocols, including limited directories and chained directories. We compared protocols that are scalable in terms of both memory overhead to a protocol that cached only private data to and to a nonscalable protocol (full-map). While the scheme that cached only private data performed fairly well, the shared data caching schemes performed better for the majority of the applications that we studied. Limited and chained directory schemes permitted the use of caches to significantly reduce the effective shared memory latency.

There is no hardware panacea for the cache-coherence problem. As with many other problems in computer architecture, good solutions balance hardware and software optimizations that combine to improve system performance. When we applied system-level optimizations to caching, we were able to improve the performance of systems with large numbers of processors.

Our work can be extended in several ways. The most straightforward extension would repeat our trace-driven evaluation using other network models.

Our research group at MIT is currently performing more detailed simulations of directory schemes, coupled with processor and network simulations, to get accurate multiprocessor performance statistics. Such simulations allow us to address the issue of hot spots, the impact of high-latency operations, and the effect of interrupting local cache accesses with external invalidation messages. We are also researching various methods for alleviating the effects of communication latency. These methods include using multithreaded processors with coherent caches, software emulation of directories, and coherence models other than sequential consistency.

Acknowledgments

It is impossible to analyze a large range of applications, programming models, and architectures without becoming indebted to a host of collaborators. Mathews Cheria laid the foundation for our analysis by writing both the postmortem scheduler with Kimming So at IBM and the cache and directory simulator. Pat Teller of New York University provided the Simple and Weather programs, and FFT was written at IBM. Harold Stone and Kimming So helped us obtain the IBM traces. Wolf-Dieter Weber and Anoop Gupta provided us with the four VAX T-bit traces, which were generated using a system developed by Steve Goldschmidt at Stanford. David Krauz wrote the Mul-T compiler and the T-Mul-T trace generator and helped analyze the results from the Mul-T application. Kirk Johnson, who wrote and traced the Speech application, is responsible for the read-only data processing results. Giao Ma and Sue-Kyoung Lee wrote the packet-switched network simulator that validated our network model.

Encore Computer Corporation provided the Multimax system that runs T-Mul-T, Digital Equipment Corporation and Harris Computer Systems provided the machines we used to manipulate gigabytes of trace data. We would also like to thank the rest of the Alewife group for putting up with our interminable trace-driven simulations.

The research reported in this article is funded by DARPA contract No. N00014-87-K-0825 and by grants from the Sloan Foundation and IBM.

**Software Developers**

TRW, the company of tomorrow, invites you to become part of our future. We have many openings in Redondo Beach, CA for Software Developers with experience in one or more of the following areas:

- Ada
- VAX/VMS FORTRAN
- C/Unix on a M68000-based Sun workstation
- PASCAL
- Software Systems Engineering
- Real Time Multi-tasking
- Device Drivers/MACRO
- S/W Modeling and Performance Simulation
- Algorithm Development
- Onboard Processing
- Radar/Signal Processing
- Mission Planning
- Image Processing
- Sensor Data Processing

If you meet our special technical needs, we would like you to send a resume to:

TRW System Development Division
One Space Park
Bldg. 02, Room 1356
Department IEEE
Redondo Beach, CA 90278

---

Craig Fields is an applications programmer for Project Athena at the Massachusetts Institute of Technology. He is also a member of the Alewif group in the institute's Laboratory for Computer Science. His research interests are parallel architectures and systems development. Fields attended MIT until 1989.

Kiyoshi Kuribara, a systems engineer at IBM Japan, is a postgraduate studying in the Department of Electrical Engineering and Computer Science of the Massachusetts Institute of Technology under an MIT Overseas Study Program scholarship from the company. His research interests are computer architecture and system performance evaluation methodology. He is carrying out research work at MIT's Laboratory for Computer Science. Kuribara received his bachelor of engineering degree from the University of Tokyo in 1981.

Anant Agarwal has been an assistant professor of electrical engineering and computer science in the Laboratory for Computer Science at the Massachusetts Institute of Technology since January 1988. His research interests include the design of scalable multiprocessor systems, VLSI processors, parallel processing software, and performance evaluation. He initiated MIT's Alewife project, which aims to design and implement a large-scale cache-coherent multiprocessor.

Agarwal received the B.Tech degree in electrical engineering from the Indian Institute of Technology, Madras, India, in 1982, and the MS and PhD degrees in electrical engineering from Stanford University in 1984 and 1987, respectively. He is a member of the IEEE Computer Society.
