Figure 1: Traditional kernel-based message passing architecture for intra-cluster communication.

- User application initiates communication.
- Socket is the interface to user application.
- TCP and UDP provide end-to-end channel for users.
- IP is for routing.
- Driver/NIC perform transmit and receive.
User Applications:

```
s = socket(SOCK_DGRAM)
bind(s,localAddr)
...
Allocate 2 msg buf
...
connect(s,remoteAddr)
...
Prepare msg[1] for sending
send(s, msg[1])
recv(s, &msg[0])
...
close(s)
```

Echo client using UDP/IP socket

```
s = socket(SOCK_DGRAM)
bind(s,localAddr)
...
Allocate 1 msg buf
...
connect(s,remoteAddr)
...
...
recv(s, &msg)
send(s, msg)
...
close(s)
```

Echo server using UDP/IP socket
1.1 – How UDP send/receive work

Figure 2: TCP/UDP/IP over DEC 21140 NIC (tulip)
UDP send operations

Socket:

- get the BSD socket structure.
- build `msghdr` structure for the sending message.
- pass control from BSD socket to INET socket.

UDP:

- get and verify the address. For connected socket, a flag is set to avoid routing.
- For unconnected socket, call routing function to get the routing table entry.
- fill in the UDP header (except checksum).

IP:

- segment large message if necessary.
- allocate a socket buffer (skbuf) and a data buffer for the sending message. The data buffer includes the message and udp/ip/ethernet headers. The ethernet header is 16-byte aligned. The data buffer is 128-byte aligned.
- fill in the IP header and calculate the IP header checksum.
**IP (continue):**
- copy the message from user space to \texttt{skbuf} and compute the message checksum at the same time.
- compute the UDP header checksum and TCP/UDP pseudo-header checksum.
- copy the UDP header to \texttt{skbuf}.

**Driver(xmit):**
- enqueue \texttt{skbuf} to \texttt{tx\_ring}.
- trigger the immediate transmit.

**NIC:**
- DMA fetch \texttt{tx\_ring} descriptor.
- DMA fetch data buffer.
- CRC checksum.
- put packet onto the wire.

**After NIC complete transmission:**
- send a interrupt signal to CPU.
- CPU calls the NIC interrupt handler to dequeue \texttt{skbuf} from \texttt{tx\_ring} and free the buffer.
UDP receive operations

when NIC receives a packet:

- DMA the incoming packet to a skb pointed by rx_ring tail descriptor.
- send an interrupt to CPU.

Driver(recv):

- determine the packet protocol id.
- push skb into a queue.
- add the NIC to the poll list, and raise a soft interrupt to trigger the bottom-half of the receive process.

IP (in bottom half):

- check IP header (length, version, checksum).
- handle IP options if any.
- reassemble IP fragments if necessary.
**UDP (in bottom half):**

- check UDP header (length, checksum).
- find the INET socket that matches the address/port.
- enqueue `skbuff` into the socket receive queue.
- wake up a sleeping process waiting for packets.

**Socket:**

- get the BSD socket structure.
- build `msghdr` structure for receiving message.
- pass control from BSD socket to INET socket.

**UDP (top half):**

- If no packet arrives and `recv()` is a blocking call, the current process will sleep.
- After being waked up, copy and checksum the message from `skbuff` to user space.
- copy the sender’s address to user space.
1.2 – UDP critical path analysis

Table 1: UDP critical time break down

Problem: **LARGE OVERHEAD!**
**Goal:** reduce software overhead to approach hardware limits.

**Quick solution:**

This idea is reasonable:

- Cluster network can be assumed to be reliable and secure. A thick protocol stack like TCP/IP is not necessary.
- An increasing number of applications are more sensitive to communication latency.

But,

- How to allow direct access yet provide protection?
- How to design an efficient, yet versatile programming interface?
- How to manage resources, in particular memory?
- How to fair share network without a kernel path?
In *user-level message passing architecture*, the operating system kernel and its centralized networking stack are removed from the critical communication path in a protected fashion, providing user applications a *user-level network interface*, through which users can directly access to their network interface. The operating system is only involved in setting up the communication.

In this way, the communicating parties can avoid intermediate copies of data, interrupts, and context switches in the critical path, thus greatly decreasing communication latency and increasing network throughput.
2.1 – VIA Overview

Figure 4: The Virtual Interface Architecture Model
Figure 5: A Virtual Interface
VipOpenNic(&nicHand)
...
VipCreateVI(&viHand)
...
Allocate 3 desc and 3 msg
Register 3 desc and 3 msg
desc[i].buf ← msg[i]
...
VipPostRecv(viHand, &desc[1])
descp ← &desc[2]
VipConnectRequest(viHand,lAddr,rAddr)
...
Prepare msg[0] for sending
VipPostSend(viHand,desc[0])
VipSendWait(viHand,&descp2)
VipPostRecv(viHand,descp)
VipRecvWait(viHand,&descp)
...
VipDisconnect(viHand)
Deregister desc and msg
VipDestroyVI(viHand)

Echo client using VIA

VipDestroyVI(viHand)

Echo server using VIA
2.2 – How M-VIA send/receive work

Figure 6: M-VIA over DEC 21140 NIC (tulip). M-VIA is a modular VIA implementation for Linux over Ethernet.
M-VIA send operations

**VipPostSend:**
- enqueue a send descriptor to the sending queue.

**Driver(xmit):**
- prepares send header, waits for device stop, gets the next send descriptor entry, and fill in the header.
- segments large packets into chunks.
- enqueue each chunk to `tx_ring`.
- trigger the immediate transmit.

**NIC:**
- DMA fetch `tx_ring` descriptor.
- DMA fetch data buffer.
- CRC checksum.
- put packet onto the wire.
After NIC complete transmission:

- send a interrupt signal to CPU.
- CPU calls the NIC interrupt handler to dequeue head entries from tx_ring, mark the descriptor complete and wake up a block process.

VipSendWait:

- check the head descriptor of the sending queue for N times. If the head descriptor is marked complete, remove it from the sending queue and return success.
- otherwise, sleep.
- after being waked up, check the head descriptor again. If the head descriptor is marked complete, remove it from the sending queue, and return success. Otherwise, return error.
M-VIA receive operations

VipPostRecv:
- enqueue a recv descriptor to the receiving queue.

when NIC receives a packet:
- DMA the incoming packet to a buffer pointed by rx_ring tail descriptor.
- send a interrupt signal to CPU.

Driver(recv):
- get a corresponding VI structure from the received packet.
- check the sequence number of the received packet.
- copy the packet from rx_ring to VI specified buffer.
- dequeue head entry from rx_ring.
- mark the descriptor complete.
- wake up a block process.
**VipRecvWait:**

- checking the head descriptor of the receiving queue for N times. If the head descriptor is marked complete, remove it from the receiving queue and return success.
- otherwise, sleep.
- after being waked up, check the head descriptor again. If the head descriptor is marked complete, remove it from the receiving queue, and return success. Otherwise, return error.

Table 2: M-VIA critical time breakdown
2.4 – M-VIA performance evaluation

![Diagram of M-VIA 1.2 with modules, library, header, and application settings.](image)

**Figure 8: Experimental Setting**
Figure 9: One-way latency vs. message size

- entirely remove socket, TCP/UDP and IP layers.
- zero copy when sending. Sending overhead is constant.
- use fast trap instead of normal system call.
- use polling instead of interrupt to avoid context switch.
• Traditional kernel-based communication has large software overhead.

• User-level communication is a good solution for intra-cluster communication.
