Pennsylvania State University*

Buffer Overflow

- Early example of a method to exploit a “memory error” in a C program
- Discovered in the 1970s
- Leveraged by the Morris Worm in 1988 – first large-scale exploit
- Leveraged by subsequent attacks in the early 2000s that led to security rethink
- Still a problem today – Check out CVEs for “buffer overflow”

Memory Error

- A **memory error** allows a program statement to access memory outside of that allocated for the variables processed in the statement
- Common case: **Buffer overflow**
 - ▶ The C language allows writes to memory addresses specified by pointers
 - `char buf[10]` – *buf* can be used as a pointer
 - ▶ C functions enable writing based on the size of the input or a length value
 - `strcpy` and `strncpy`
 - ▶ However, **does not ensure** writes only within the buffer

Morris Worm

- Robert Morris, a 23-year old Cornell PhD student
 - ▶ Wrote a small (99 line) program
 - ▶ Launched on November 3, 1988
 - ▶ Simply disabled the Internet
- Used a buffer overflow in a program called *fingerd*
 - ▶ To get adversary-controlled code running
- Then spread to other hosts – cracked passwords and leveraged open LAN configurations
- Covered its tracks (set its own process name to *sh*, prevented accurate cores, re-forked itself)

Process Address Space

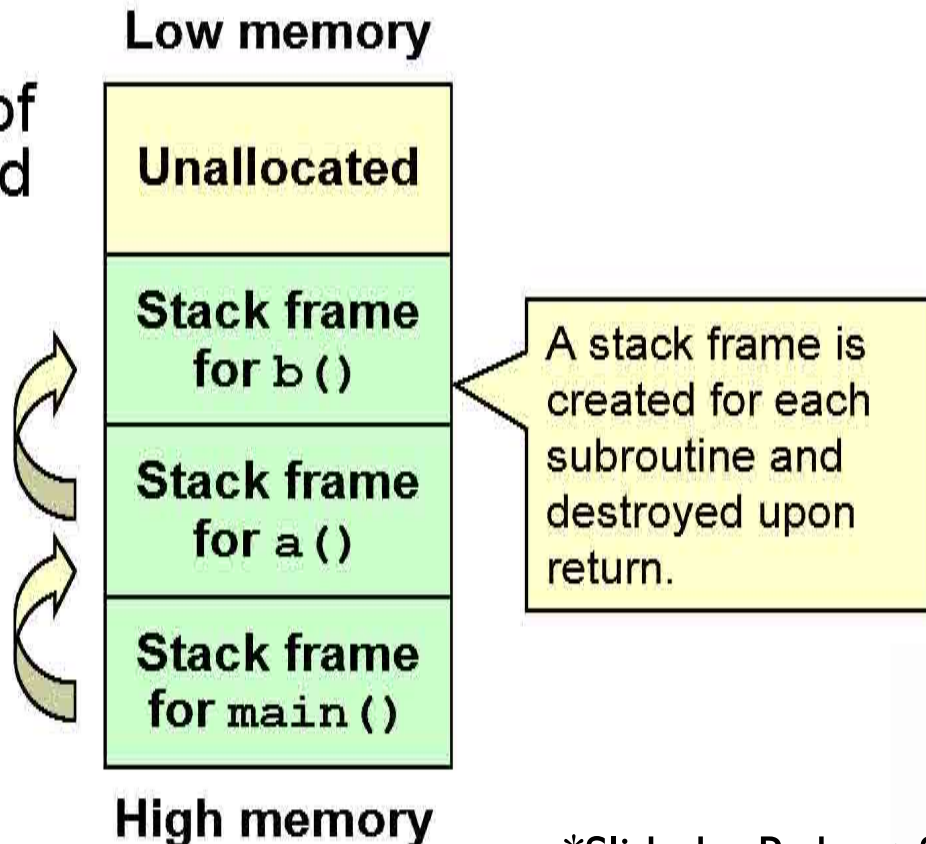

- **Text**: static code
- **Data**: also called heap
 - static variables
 - dynamically allocated data (malloc, new)
- **Stack**: program execution stacks

- For implementing procedure calls and returns
- Keep track of program execution and state by storing
 - ▶ local variables
 - ▶ arguments to the called procedure (callee)
 - ▶ return address of the calling procedure (caller)
 - ▶ ...

Stack Segment

The stack supports
nested invocation calls

Information pushed on
the stack as a result of
a function call is called
a frame

*Slide by Robert Seacord

Stack Frames

- Stack grows from high mem to low mem addresses
- The **stack pointer** points to the current “top of the stack” – last thing pushed on the stack (that matters)
 - ESP in Intel architectures
- The **frame pointer** points to the start of the current frame
 - also called the base pointer
 - EBP in Intel architectures
- The stack is modified during
 - function calls, function prologue, function epilogue and operations on stack variables (locals and args)

A Running Example

```
void function(int a, int b) {  
    char buffer[12];  
    gets(buffer);  
    return;  
}
```

```
void main() {  
    int x;  
    x = 0;  
    function(1,2);  
    x = 1;  
    printf("%d\n",x);  
}
```

Run “gcc -S -o example.s example.c” to
see its assembly code

Function Calls

function (1,2)

<code>pushl \$2</code>
<code>pushl \$1</code>
<code>call function</code>

push the 2nd arg to stack

push the 1st arg to stack

push the ret addr onto the stack,
and jumps to the function

Function Calls: Stacks

Before

After

Function Initialization

```
void function(int a, int b) {
```

<code>pushl %ebp</code>
<code>movl %esp, %ebp</code>
<code>subl \$12, %esp</code>

saves the prior frame pointer

sets the new frame pointer

allocate space for local
variables

Function prologue

Function Initialization: Stacks

Before

After

Function Return

return;

<code>movl %ebp, %esp</code>
<code>popl %ebp</code>
<code>ret</code>

restores the old stack pointer

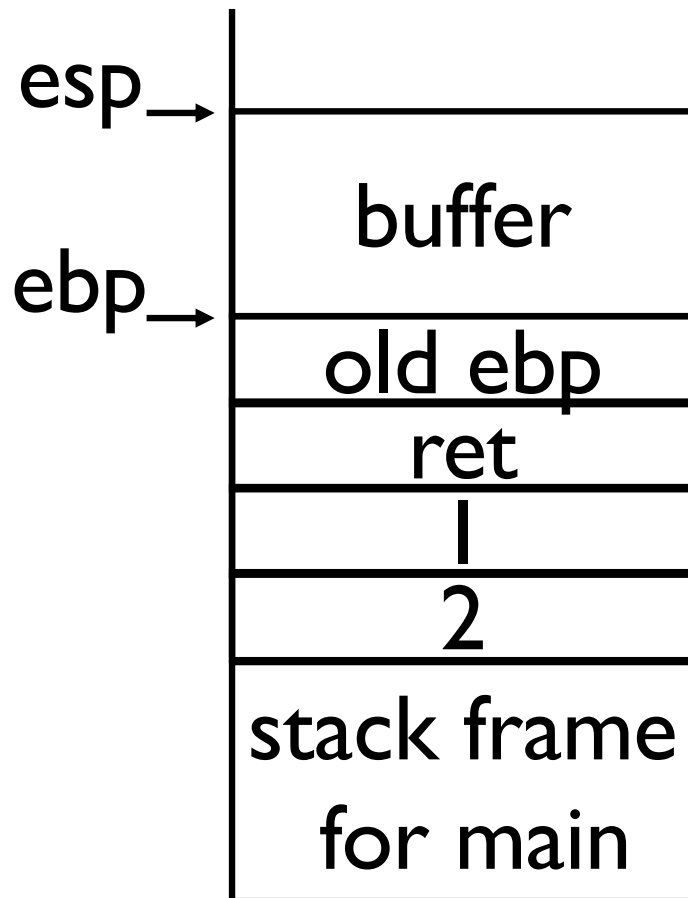

restores the prior frame pointer

gets the return address at
current stack pointer, and
jumps to it

Function epilogue

Function Return: Stacks

Before

After

Return to Calling Function

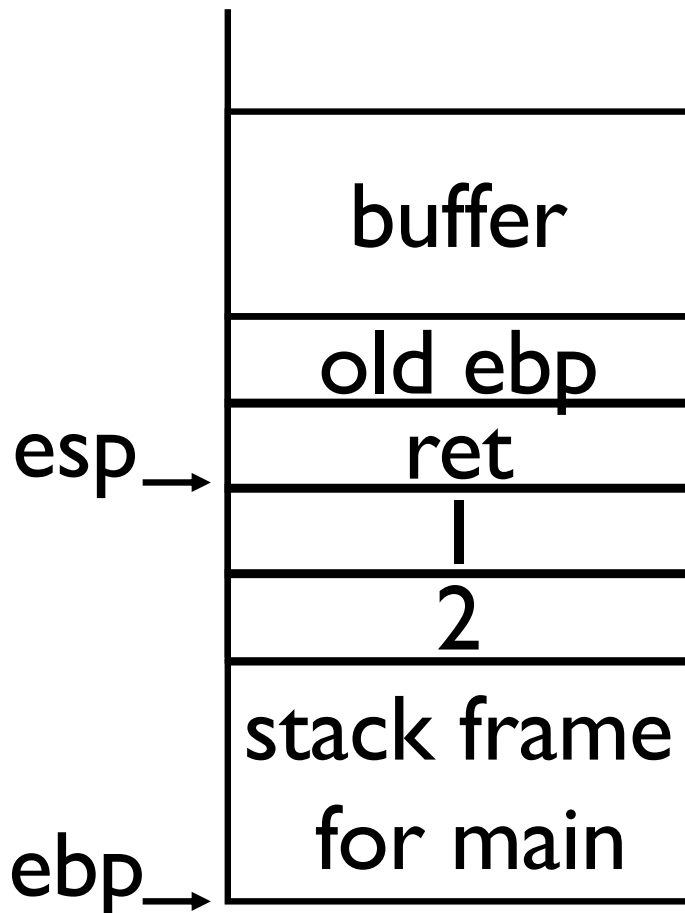

In main again – following return...

<code>pushl \$2</code>
<code>pushl \$1</code>
<code>call function</code>
<code>addl \$8, %esp</code>

restores the stack
pointer for caller

Return to Calling Function: Stacks

Before

After

A Running Example

```
void function(int a, int b) {  
    char buffer[12];  
    gets(buffer);  
→   return;  
}
```

```
void main() {  
    int x;  
    x = 0;  
    function(1,2);  
    x = 1;  
    printf("%d\n",x);  
}
```

Overwriting the Return Address

```
void function(int a, int b) {  
    char buffer[12];  
    gets(buffer);  
  
    int* ret = (int *)buffer+?;  
    *ret = ?;  
  
    return;  
}
```

Overwriting the Return Address

```
void function(int a, int b) {  
    char buffer[12];  
    gets(buffer);  
  
    int* ret = (int *) buffer+16;  
    *ret = *ret + 1;    // assuming one-byte store  
  
    return;  
}
```

The output will be 0

```
void main() {  
    int x;  
    x = 0;  
    function(1,2);  
    x = 1;  
    printf("%d\n", x);  
}
```

the original return address

the new return address

Previous Attack

- Not very realistic
 - ▶ Attackers are usually not allowed to modify code
 - ▶ Threat model: the only thing they can affect is the input
 - ▶ Can they still carry out similar attacks?
 - **YES**, because of possible buffer overflows

Buffer Overflows

- A **buffer overflow** occurs when data is written outside of the boundaries of the memory allocated to a particular data structure (buffer)
- Happens when buffer boundaries are neglected and unchecked
- Can be exploited to modify memory after buffer
 - ▶ Stack: **return address**, local variables, **function pointers**, etc.
 - ▶ Heap: data structures and metadata (next time)
- Also, a **buffer underflow** to modify memory prior

Smashing the Stack

- Occurs when a buffer overflow overwrites other data in the program stack
- Successful exploits can **overwrite the return address** on the stack enabling the execution of arbitrary code on the targeted machine
- What happens if we input a large string?
- `./example`
 - ▶ `ff`
- Segmentation fault – why is that?

What Happened?

```
void function(int a, int b) {  
    char buffer[12];  
    gets(buffer);  
    return;  
}
```

If the input is large, then `gets(buffer)` will write outside the bound of buffer, and the return address is overwritten – with “ffff” (in ASCII), which likely is not a legal code address – **seg fault**

Figure Out A Nasty Input

```
void function (int a, int b) {  
    char buffer[12];  
    gets(buffer);  
    return;  
}
```

```
void main() {  
    int x;  
    x = 0;  
    function(1,2);  
    x = 1;  
    printf("%d\n", x);  
}
```

A nasty input puts the return address after `x=1`.

“Arc” injection – new control flow

Injecting Code

```
void function (int a, int b) {  
    char buffer[12];  
    gets(buffer);  
    return;  
}
```

```
void main() {  
    int x;  
    x = 0;  
    function(1,2);  
    x = 1;  
    printf("%d\n",x);  
}
```

The injected code can do anything.
E.g., download and install a worm

- Attacker creates a malicious argument—a specially crafted string that contains a pointer to malicious code provided by the attacker
- When the function returns, control is transferred to the malicious code
 - ▶ Injected code runs with the permission of the vulnerable program when the function returns.
 - ▶ Programs running as **root** or other elevated privileges are normally targeted
 - Programs with the **setuid bit** on

Injecting Shell Code

- This brings up a shell (**logical view** – real later)
- Adversary can execute any command in the shell
- The shell has the same privilege as the process
- Often, a process with the root privilege is attacked

Injecting Shell Code

- How do you invoke “execve” using injected code?

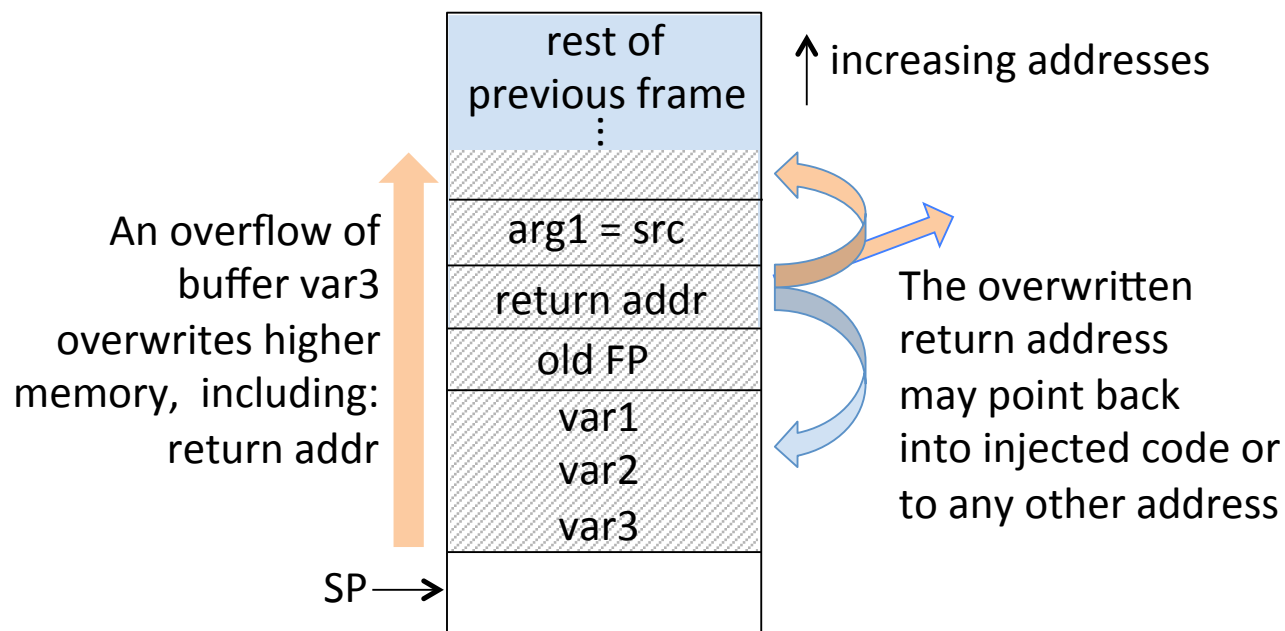

Figure 6.5: Buffer overflow of stack-based local variable.

Injecting Shell Code

- Inject the address of the “**execve**” function **at the return address or elsewhere in stack reference by the return address**
 - ▶ “execve” is a function in *libc* that is dynamically linked into the process address space
- To invoke a function in a library it must be able to find that address itself as well
- **How is that done?** Your program calls “execve” thru a stub (procedure linkage table), which retrieves the address set at link time (in the global offset table)

Injecting Shell Code

- Example of PLT code (from `objdump -dl`)

0x08048730 <execve@plt>:

```
8048730:  ff 25 1c d1 04 08      jmp     *0x804d11c
8048736:  68 28 00 00 00      push   $0x28
804873b:  e9 90 ff ff ff      jmp     80486d0
```

0x08048740 <strncpy@plt>:

```
8048740:  ff 25 20 d1 04 08      jmp     *0x804d120
8048746:  68 30 00 00 00      push   $0x30
804874b:  e9 80 ff ff ff      jmp     80486d0
```

Injecting Shell Code

- Overwrite return address with address of code to run next (e.g., `execve@plt`)
 - What address?
- Provide argument(s) above – pointer to “/bin/sh” command
 - Where to put it?
- And then “null” for last arg (env)

Any C(++) code acting on untrusted input is at risk

- Code taking input over **untrusted network**
 - E.g., sendmail, web browser, wireless network driver,...
- Code taking input from **untrusted user** on multi-user system,
 - esp. services running with high privileges (as ROOT on Unix/Linux, as SYSTEM on Windows)
- Code processing **untrusted files**
 - that have been downloaded or emailed
- Also embedded software, e.g., in devices with (wireless) network connection such as mobile phones with Bluetooth, wireless smartcards in new passport or OV card, airplane navigation systems, ...

Take Away

- **Memory errors** enable processes to write to memory outside the expectation range
- The classic example is the **buffer overflow**, which is still a common attack vector today
- A buffer overflow vulnerability allows an adversary to overwrite the memory beyond the buffer on the stack
 - ▶ But runtime state is also on the stack – return address
- We discussed methods to inject and reuse code
- Available defenses are not complete
