GO: Out-Of-Core Partitioning of Large Irregular Graphs

Gurneet Kaur

Rajiv Gupta  
CSE Dept., UC Riverside

Abstract—Single-PC, disk-based processing of large irregular graphs has recently gained much popularity. At the core of a disk-based system is a static graph partitioning that must be created before the processing starts. By handling one partition at a time, graphs that do not fit in memory are processed on a single machine. However, the multilevel graph partitioning algorithms used by the most sophisticated partitioners cannot be run on the same machine as their memory requirements far exceed the size of the graph. The popular memory efficient Mt-Metis graph partitioner requires 4.8× to 13.8× the memory needed to hold the entire graph in memory. To overcome this problem, we present the GO out-of-core graph partitioner that can successfully partition large graphs on a single machine. GO performs just two passes over the entire input graph, partition creation pass that creates balanced partitions and partition refinement pass that reduces edgecuts. Both passes function in a memory constrained manner via disk-based processing. GO successfully partitions large graphs for which Mt-Metis runs out of memory. For graphs that can be successfully partitioned by Mt-Metis on a single machine, GO produces balanced 8-way partitions with 11.8× to 76.2× fewer edgecuts using 1.9× to 8.3× less memory in comparable runtime.

Index Terms—irregular graphs, out-of-core processing, multilevel graph partitioning

I. INTRODUCTION

Graph analytics is employed in many domains to gain insights by analyzing large graphs representing entities and interactions among them. Real world graphs often contain millions of vertices and billions of edges (see Table I), and iterative graph analytics queries require multiple passes over the graph until convergence. Therefore, there has been a great deal of interest in developing scalable graph analytics systems that exploit parallelism available on distributed systems [2], [4], [16], [17]) as well as shared memory systems [18], [21]. Before parallel or distributed analytics on large graphs can be performed, they typically must first be partitioned. In context of distributed systems the graph is partitioned across multiple machines such that each machine is primarily responsible for computations that operate on its assigned partition. In context of a single shared-memory machine, the graph is partitioned to enable out-of-core or disk-based processing of a large graph on a single machine [12], [22], [23], [25]. When the graph is too large to fit in the memory available on the machine, it is divided into smaller partitions and stored on disk. This enables partitions to be loaded one at a time into memory and processed.

For superior performance, partitioning algorithms endeavor to create partitions that are well balanced and minimize edgecuts (i.e., number of edges that cross partition boundaries). Although the problem of graph partitioning is known to be NP-hard [1], highly effective multilevel graph partitioning algorithms have been developed and are widely used [5]–[8], [24]. A large graph goes through a series of coarsening phases which, by merging vertices, produces significantly smaller graphs at each subsequent level. Once a sufficiently small graph is obtained, it is partitioned. Next this partitioning is projected to the coarsened graph at the next level to obtain its partitioning that is further refined using the Kernighan-Lin algorithm [10] to reduce edgecuts. This preceding step is repeated through the levels eventually producing a partitioning for the original full graph. Many implementation frameworks for multilevel graph partitioning are available for distributed systems (e.g., ParMetis [9], Scotch [19], KaFFPa [20]). These frameworks enable end-to-end processing of large graphs on distributed systems as both partitioning and subsequent analytics tasks can be performed on the same distributed platform.

While a framework that implements multilevel graph partitioning on a single shared-machine, called Mt-Metis [14], [15], is also available, it does not enable end-to-end processing of large graphs on a single machine because Mt-Metis requires that not only the input graph be held in memory but also the coarsened graphs. Since the out-of-core processing of large graphs is required in the first place because the entire graph does not fit in memory, executing Mt-Metis to partition such a graph fails as it runs out of memory. Therefore current out-of-core graph processing systems employ very simple partitioning

schemes that simply distribute vertices among partitions [22]. Consequently, end-to-end processing of large graphs on a single machine using sophisticated partitioners is an open problem.

We present GO, an Out-of-core Graph Partitioner, that given a fixed amount of memory on a machine, successfully partitions large graphs that cannot be held in the given amount of memory. GO performs just two passes over the entire input graph, the partition creation pass that creates balanced partitions and the partition refinement pass that reduces edgecuts. Both passes are designed to function in a memory constrained manner. During the partition creation phase parallel threads read the graph from disk and assign vertices, along with their adjacency lists, to different partitions. Once the available memory is full, the subpartitions created thus far are written to disk to free up the memory. Thus, the threads can resume reading the remainder of the graph from disk and partitioning it. This process produces an initial partitioning that resides on disk. Next the partition refinement phase reads portions of all partitions into memory, refines these subpartitions against each other using the KL-algorithm [10], and maintains the refined partitioning. This process is repeated until entire initial partitioning has been read and processed to generate the final refined partitioning.

Since GO performs partitioning without creating coarsened graphs, it is a single level partitioner with greatly reduced memory requirement. In other words, given a graph that can be held in available memory, GO can partition the graph without requiring the initial partitioning to be written to and then read back from disk during refinement. That is, entire partitioning can be performed in-memory. On the other hand, since Mt-Metis requires additional memory to hold coarsened graphs, total memory that it requires to hold all graphs is several times (4.8× to 13.8×) the memory needed to simply hold the original graph. Thus, Mt-Metis cannot partition the graph successfully even if enough memory is available to hold the entire input graph in memory. The quality of partitions produced by GO were found to be superior to those produced by Mt-Metis both in the terms of balance and edgecuts. This is due to careful design of initial partitioning algorithm and our modified application of KL-algorithm.

Our experiments with GO prototype on nine input graphs of varying sizes show that GO can successfully partition large graphs for which Mt-Metis runs out of memory on the machine used. For graphs that can be successfully partitioned by Mt-Metis on a single machine, GO produces balanced 8-way partitions with 11.8× to 76.2× fewer edgecuts using 1.9× to 8.3× less memory and comparable runtime. To further compare the quality of partitions produced by GO and Mt-Metis, we used these partitions to execute PageRank and Weakly Connected Components workloads on the GridGraph [25] disk-based processing system. Running times of GridGraph using GO partitions were always found to be less than those using Mt-Metis partitions.

II. LIMITATION OF MULTILEVEL PARTITIONING

Given a graph \( G = (V, E) \), the goal of \( k \)-way graph partitioning is to partition \( V \) into \( k \) non-empty disjoint subsets \( V_1, V_2, \ldots, V_k \). In general all vertices and edges in the graph have a weight but to simplify the discussion let us assume all weights are one. The quality of resulting partition is measured by its balance and edgecuts. Balance is defined as \( k \sum_{i=1}^{k} |V_i| / |V| \), which is ideally 1, and when it exceeds 1, the greater the value the greater is the degree of imbalance. Edgecuts corresponds to the number of edges that connect vertices from different partitions. A partitioning with lower edgecuts is preferred.

The multilevel graph partitioning scheme employed by Mt-Metis [14], [15] has three phases. The Coarsening Phase transforms the given graph \( G \) into a sequence of smaller graphs \( G_1, G_2, \ldots, G_L \) such that \( |V| > |V_1| > |V_2| > \cdots > |V_L| \). The Partitioning Phase generates \( k \)-way partitioning \( P_L \) of \( G_L \). The Uncoarsening Phase projects \( P_L \) back to partitioning \( P \) of \( G \) going through intermediate partitions \( P_{L-1}, P_{L-2}, \ldots, P_1 \). A detailed evaluation of Mt-Metis carried out by Lasalle and Karypis [14] shows that in comparison to ParMetis [9] and Scotch [19] which are both distributed implementations, the memory requirements of Mt-Metis is significantly lower. In fact, the memory requirements of Mt-Metis are only slightly higher than the serial implementation KMetis [7] – the extra memory is needed primarily for thread local data structures and it increases with the number of threads. Moreover, Mt-Metis is optimized to work for irregular graphs [15]. Table III compares Mt-Metis and KMetis in terms of edgecuts, peak memory used, and execution times on 425GB machine.

However, multilevel algorithms have a high memory requirement because in addition to holding \( G \) in memory, the coarsened graphs \( G_1, G_2, \ldots, G_L \) must also be held in memory. While the original graph size is \( |E| + |V| \), the cumulative graph size of coarsened graphs is \( \sum_{i=1}^{L} |E_i| + |V_i| \). Thus, the combined size of the original graph and the coarsened graphs is \( 1 + \sum_{i=1}^{L} |E_i| + |V_i| \) times the size of the original graph.

We collected the values of this ratio for the sample graphs in Table I by running Mt-Metis and the results are presented in Table II. All experiments in this paper were performed on a machine with 32 cores (2 sockets, each with 16 cores) with Intel Xeon Processor E5-2683 v4 processors, 425 GB memory, 1TB SATA Drives, and running CentOS Linux 7. We observe that the ratio varies from 4.8× to 13.8× for the first six graphs. The number of levels of coarsening \( L \) is also given for each run. We could not collect the data for the three largest graphs because, on the machine used, Mt-Metis ran out of memory.

Next we present GO, a two-phase algorithm that does not employ multilevel partitioning, and can partition the larger graphs even when provided with memory less than what is needed to hold the original graph.

III. GO: OUT-OF-CORE GRAPH PARTITIONER

Given a limited amount of memory that cannot even hold the input graph in adjacency list format, GO uses the given memory to form memory buffers that are used by multiple threads to perform parallel graph partitioning in two phases: Initial Partition Creation; and Partition Refinement to Create Final Partitions. Both phases are designed to function in memory...
vertices to create balanced initial partitions and accumulating the in-memory buffers, the final refined partitions are available in-memory portions of the partitions are refined against each other. Portions of partitions from InfiniMem second phase once again the in-memory buffers are created, object store \(11\)) as an ordered sequence of batches. In the second phase threads read the graph from disk in parallel, assigning vertices to source vertices, a balanced partitioning is ensured. The above process is repeated as long as there is room in the buffers to accommodate more of the graph. Once some buffer \(B_\alpha\) is full, its contents are written to the disk, that is, \(B_\alpha\) is emptied and processing of the graph is resumed. Emptying of \(B_\alpha\) is referred to as writing of a batch to disk. When the entire graph has been processed, all buffers are emptied and the partitioned graph is available on disk. On disk the graph is now organized according to partitions, where each partition is made up of series of batches. Consequently, after this phase, the next phase (refinement) can read each partition using blocked serial reads of its batches from the disk. While the partitioned graph is written to disk, an auxiliary in-memory  \(PID\) array, indexed by vertex id, remembers the partition ids of all vertices.

Note that if the buffers are large enough to accommodate the entire graph during the first phase, then the initial partitions are not written to disk and re-read for refinement. Instead the refinement is also fully carried out in memory and final partitions are finally output to the disk. In subsequent subsections we present each of these phases in greater detail.

A. Memory Constrained Initial Partition Creation

For \(k\)-way partitioning of graph \(G\), the memory available to the GO partitioner is divided into \(k\) buffers \(B_1, B_2 \cdots B_k\), one for each partition. The graph is read using blocked serial reads from disk. Each source vertex \(v\) is assigned to some partition \(P_i\), and the vertex \(v\) and its adjacency list \(Adj(v)\) are stored in buffer \(B_i\). By using a simple hashing function for assigning partitions to source vertices, a balanced partitioning is ensured. The above process is repeated as long as there is room in the buffers to accommodate more of the graph. Once some buffer \(B_\alpha\) is full, its contents are written to the disk, that is, \(B_\alpha\) is emptied and processing of the graph is resumed. Emptying of \(B_\alpha\) is referred to as writing of a batch to disk. When the entire graph has been processed, all buffers are emptied and the partitioned graph is available on disk. On disk the graph is now organized according to partitions, where each partition is made up of series of batches. Consequently, after this phase, the next phase (refinement) can read each partition using blocked serial reads of its batches from the disk. While the partitioned graph is written to disk, an auxiliary in-memory  \(PID\) array, indexed by vertex id, remembers the partition ids of all vertices.

Fig. 1: Overview of Out-of-Core GO Graph Partitioning.
Parallelization: To parallelize the I/O and processing, we use $t$ threads that read from disk in parallel and create the partitions in parallel. To ensure that the $t$ threads do not have to synchronize with each other when updating the buffers, each buffer is subdivided into $t$ sub-buffers, one for each thread. This leads to the organization of the graph as shown in Figure 2 where the number of in-memory buffers is $t \times k$. Corresponding to each of $t \times k$ buffers, the disk contains a series of batches that are written to disk when the buffers are emptied.

Vertex-Ordered Representation: Note that the source vertices in the original graph, and corresponding adjacency lists, are organized on disk in the order of source vertex ids. Thus, they are read in the order of source vertex ids by the above partitioning phase, they appear in the order of source vertex ids in $B_v$’s, and thus appear in order inside each batch written to disk. To illustrate this phase let us consider the example shown in Figure 3. In Figure 3(a) an example graph and its adjacency list representation is shown. Let us assume that we are carrying out 2-way partitioning using 2 threads and hence the memory is organized into 4 buffers. Figure 3(b) shows the representation of the graph where all of the graph has been read and processed, part of it has been written to the disk in its batched partition form while part resides in memory buffers. Here each buffer has been emptied once. Once the buffers are emptied, the completed initial partitioning of the graph that resides on the disk is shown in Figure 3(c). Note that the contents of in-memory buffers and on-disk batches are all ordered according to vertex ids of source vertices in them.

Split Adjacency Lists for Irregular Graphs: In out-of-core processing by systems such as GraphChi [12] and GridGraph [25], the graph partitions are represented as a subset of edges from the graph. The edges present in the subgraph corresponding to a partition are essentially contained in the partition’s representation. Balancing edges across partitions is important because the work performed by analytics tasks (e.g., single source shortest paths) is proportional to the number of edges. Since power-law graphs, due to their irregular skewed degree distribution, contain vertices with very high degrees, we obtain a balanced partitioning by distributing the edges incident to such vertices across the partitions. This can be carried out simply by adding a threshold parameter $\delta$ such that when source vertex $v$ is processed by a thread, after placing $\delta$ edges in its current partition, the partition is changed causing the next $\delta$ edges to be placed in a different partition. This approach enables the edges for vertex $v$ to be split across all $k$ partitions in batches of $\delta$.

Note that it is also possible for the adjacency list of some vertex $v$ to get split because the buffer to which the list is being written to has become full. This can be observed in Figure 3(c) where vertex 7 is assigned to partition 1 and its adjacency list consisting of two vertices, 6 and 4, are split across two consecutive batches on disk. However, note that in this kind of splitting, the adjacency list is not split across partitions but rather it is split across batches that belong to the same partition. Moreover, as we will show later, when partitions are read from their batches in the refinement phase, these split adjacency lists will be merged together.

B. Memory Constrained Partition Refinement

For a $k$-way partitioning, the refinement phase is executed in parallel by $k$ threads where each thread is assigned the task of refining a single partition. The memory available is divided into $k$ buffers of equal size. All threads ($T_i$s), in parallel, load as much of the subgraphs ($wP_i$s) of their respective assigned initial partitions ($P_i$s) into their buffers ($Buffer(T_i)$s). After refining the loaded $wP_i$’s against each other, the buffers are loaded again and refined. This process continues until the entire graph has been refined and final partitioning has been found.

Parallel Loading: When buffer $Buffer(T_i)$ is loaded from partition $P_i$ the vertices assigned to $P_i$ are loaded in increasing order of vertex id. This is achieved by performing a merge sort across batches written to $P_i$ by different threads.
Note that when vertices and their adjacency lists are loaded into $Buffer(T_i)$ in this fashion, if the adjacency list of a vertex $v$ in $P_i$ had been split across different batches due to emptying of filled buffers in the initial partitioning phase, then the split adjacency list of $v$ will get merged during loading. Consequently, after loading, the contents of $Buffer(T_i)$ are organized as follows. A low degree vertex $v_i$ that is assigned to a unique partition $P_i$, appears in $Buffer(T_i)$ along with $\text{Adj}(v_i)$, its complete adjacency list. A high degree vertex $v_h$ whose edges are spread across all $k$ partitions appears in each $Buffer(T_v)$ along with the complete subset of its adjacency list assigned to each partition $P_v$.

**Refinement:** The goal of refinement using the Kernighan-Lin (KL) algorithm [10] is to reduce edgecuts in the existing partitioning by swapping pairs of vertices between partitions. Doing so does not alter the balance of the partitions that is achieved during the initial partitioning phase, the swap operations are chosen merely to reduce edgecuts. The initial partitioning is held in memory in $\text{PID}[\ast]$ array where using vertex id to index the array, we can read the partition id of the vertex. When swap operations are applied, $\text{PID}[\ast]$ contents are modified to reflect the change in partitioning.

Given a pair of vertices $(v, w)$ from two different partitions, $\text{PID}[v]$ and $\text{PID}[w]$, the decision to swap $v$ and $w$ between the two partitions is based upon the extent to which the swap reduces edgecuts, which is also called the GAIN. The **external cost** of $v$ with respect to $\text{PID}[w]$ (i.e., $EC(v) \setminus \text{PID}[w]$) is the number of edges from $v$ to vertices in $\text{PID}[w]$. The **internal cost** of $v$, $IC(v)$, is the number of edges from $v$ to vertices in $\text{PID}[v]$. If the difference between external and internal costs of $v$ and $w$, $D(v) = EC(v) \setminus \text{PID}[v] + IC(v)$, are both positive, then swapping of the vertices will definitely reduce edgecuts. The GAIN is the sum $D(v) + D(w)$ if $v$ and $w$ are not directly connected by an edge; otherwise it is $D(v) + D(w) - 2$.

When refining a pair of partitions against each other, all pairs of vertices are considered and the one that provides the highest GAIN are chosen for swapping. This process is repeated – each application is called a Pass that finds one pair to swap – until no more pairs with positive GAIN are available.

**Taming KL-algorithm’s Complexity for Large Graphs:** In large graphs with millions of vertices in each partition, it is not practical to consider every pair of vertices from every pair of partitions and consider them for swapping. To reduce the complexity we first observe that only **boundary vertices** – vertices that have edges cut by the initial partition – for a pair of partitions need to be considered during refinement. To further lower the complexity of refinement we limit the scope of refinement by dividing boundary vertices belonging to each partition into equal-sized NUMINTS intervals. When refining two partitions with respect to each other, only all pairs of vertices from corresponding intervals in the two partitions are considered. This greatly reduces the pairs considered and hence the cost of refinement. Note that high-degree vertices are not included in such pairs as, having partitioned their edges across partitions, their is no benefit from swapping them. The low degree vertices are plentiful in a large irregular graph and hence refinement of intervals that are smaller subgraphs is still highly effective as will be observed from our experimental results for GO in comparison to Mt-Metis.

**Interval-based Algorithm and Example:** Algorithm 1 presents the complete algorithm of our refinement phase. Lines 4-15 show threads loading portions of partitions into buffers in parallel, identifying boundary vertices, dividing them into intervals, and calling $\text{REFINE_PARTITION}$ to refine partitions. Lines 16-33 show the function including how a partition refines

```
We study the scalability of GO with increasing graph size and varying memory availability. For modest sized graphs that could be successfully partitioned by both GO and Mt-Metis, we compare the partitions produced by both the systems in terms of the number of edgecuts, balance and peak memory used in handling graphs of varying sizes.

The graph partitioning experiments were performed on a machine with 32 cores (2 sockets, each with 16 cores) with Intel Xeon Processor E5-2683 v4 processors, 425 GB memory, 1TB SATA Drives and running CentOS Linux 7. Table I includes graphs of varying sizes ranging from 15.5 million edges to 3.3 billion edges. This allows us to compare the scalability of partitioning algorithms and demonstrate that eventually for large graphs Mt-Metis runs out of memory while GO can successfully partition them even when only given part of the memory is available on the machine used in the experiments.

Our evaluation considers the following partitioning algorithms:

- **GO-100** corresponds to the amount of memory so the graph fits in memory and initial partition is not written to and re-read from disk.
- **GO-75, GO-50, and GO-25** correspond to running GO with 75%, 50% and 25% of graph in memory. GO will need to write and re-read the initial partition from disk.
- **Mt-Metis** is a multithreaded version of Metis [14]. We compare GO’s performance with Mt-Metis 0.6.0 that incorporates enhanced coarsening scheme [15] for graphs with highly variable degree distribution (e.g., power-law).

### A. Quality of Partitions: Edgecuts and Balance

We demonstrate that GO can successfully partition all graphs in Table I using varying amounts of memory that holds 100%, 75%, 50%, or 25% of the graph. Since different configurations have different amounts of memory available, the partitionings they produce are different. We compare the quality of partitions produced using Mt-Metis with the various GO configurations. Table IV and Figure 5 presents edgecuts data while Table V presents the balance data for partitionings produced. For Mt-Metis no data is presented for the three largest graphs (TW, TM and UK07) because it runs out of memory in the coarsening phase and terminated (indicated by \( \times \) in the tables).

**Edgecuts:** From the number of edgecuts given in Table IV, we observe that the number of edgecuts produced by all GO configurations are typically far fewer than Mt-Metis, i.e., irrespective of the amount of memory available to GO. This is because the interval size employed by the KL algorithm during the refinement is similar for all the GO configurations. The variation in edgecuts for different GO configurations is due to the difference in refinement intervals caused by batches merged during the partition refinement phase. Mt-Metis creates 8-way/16-way/24-way partitioning with 11.8/4.2/2.1× to 76.2/28.9/10.3× more edgecuts than GO-100. And this is in spite of GO-100 using much less memory as, being a single-level algorithm, it does not create coarsened graphs. As expected, the percentage of edges that are cut increases with number of partitions.
When we look at the ratio of edgecuts for Mt-Metis and GO-100, we also make another observation. The higher the ratio for the input graph, the higher is the edgecuts ratio of Mt-Metis over GO-100. Among the six graphs that are successfully handled by Mt-Metis, the three largest \( \frac{|E|}{|V|} \) ratios are 38.1 for OK, 31.1 for WK, and 18.7 for PK. Their Mt-Metis over GO-100 edgecut ratios are the worst – 76.2× for OK, 68.7× for WK, and 24.2× for PK. In other words, GO is more effective in dealing with irregular nature of graphs.

Finally, Figure 5 presents the percentage of edges that are cut by partitioning. As we can see, the percentage is generally greater for smaller graphs than for larger graphs, the edgecut percentage increases with the number of partitions.

**Balance of partitions:** Next we examine how well balanced are the partitions that are produced. We present the percentage of vertices that belong to the largest partition in a partitioning in Table V. Note that the ideal percentage for best balance is 12.5% for 8-way, 6.25% for 16-way, and 4.17% for 24-way partitioning. We observe that for seven out of nine graphs – FL, PK, OK, WK, UK2002, TW, and UK2007 – GO-100 produces almost perfect partitioning. On the other hand, with Mt-Metis the largest partitions vary from 12.54% to 16.65% in size. Thus, the partitions generated by GO-100 are more balanced and have fewer edgecuts than partitions produced by Mt-Metis. When GO is given less memory, balance of partitions is not adversely impacted but only very slightly. The highly balanced partitions produced by GO is due to its superior initial partitioning phase. This is because the swapping of vertices performed during refinement, by design, reduce the edgecuts without altering the balance of the partitions.

**B. Memory Usage**

Table VI (Left) shows the peak memory used by GO and Mt-Metis for varying the number of partitions. The peak memory is noted using the `top` utility on Linux. For the first six graphs, since Mt-Metis could successfully partition the graphs, we calculate the ratio between peak memory used by Mt-Metis versus that used by GO configurations.

From the data in Table VI and Table VII we observe the following. As expected, GO-100 is far more memory efficient than Mt-Metis as GO is a single level algorithm while Mt-

Metis is a multilevel algorithm that must additionally hold coarsened graphs in memory. For first six graphs, GO-100 uses 1.9× to 8.3× lesser amount of memory than Mt-Metis for an 8-way partitioning. For producing greater number of partitions (i.e., 16 and 24), both GO-100 and Mt-Metis require greater amount of memory although this increase is modest (less than 10%). For the largest three TW, TM, and UK2007 graphs, GO-100 uses 29.8-32.6GB, 72.9-135.6GB, and 79-85.7GB of memory respectively. Given that typically Mt-Metis uses many times the memory used by GO-100, it is not surprising that Mt-Metis runs out of memory and fails to partition the graphs.

The $|E|$ ratio impacts the memory used by the algorithms, much more so for Mt-Metis than for GO-100 resulting in the following observations. Although the sizes of WK and UK2002 are fairly close, their $|E|$ ratios are quite different – 31.1 for WK versus 14.1 for UK2002. This impacts the relative memory usage of Mt-Metis and GO. As Table VII shows Mt-Metis uses 7.3× for WK and 1.9× for UK2002 in comparison to GO-100. This is because the coarsened graphs for Mt-Metis contain greater numbers of edges for WK than for UK2002 causing greater need for additional memory by WK than UK2002.

The memory used by GO-25 is at least four times less than the memory used by GO-100. The exception is the TM input graph for which GO-100 uses around 1.5× to 2× the memory used by GO-25. This is because TM has the smallest $|E|$ ratio of 1.6 and hence edges account for smaller fraction of memory needs. In fact the auxiliary array for holding partition ids of vertices accounts for significant fraction of memory. Thus, reducing buffer memory impacts peak memory consumption far less than for all other graphs.
Table VIII presents the I/O times of writing/reading of initial partitioning to/from InfiniMem is small compared to rest of GO-25 of partitions, and amount of memory available to run. We observe that typically GO-100 exceeds the execution times for Mt-Metis are roughly 2× faster than GO-100 while for WK, Mt-Metis runs 1.6× slower. Nevertheless, GO-100 produces partitioning with fewer edgecuts than Mt-Metis for both UK2002 and WK.

The runtime of GO scale with graph size ranging from few seconds for the smallest graph to roughly 32 minutes for large graphs. Let us compare the execution times of GO-100 with GO-25. We observe that typically GO-25 exceeds the execution time of GO-100 by less than 50%. For the largest graph of UK2007 with over 3.3 billion edges, the execution time of GO-25 exceeds that of GO-100 by 8.5%, 13.4%, and 6.5% for 8-way, 16-way, and 24-way partitionings. Thus, we see that the runtimes of GO scale well with graph size, number of partitions, and amount of memory available to run.

Finally, we observed that the I/O times of GO-100 differ from the I/O times of GO-25 only by a small amount because the I/O performed by the out-of-core feature is highly efficient. Table VIII presents the I/O times of writing/reading of initial partitioning to/from InfiniMem is small compared to rest of the I/O time (numbers in parenthesis in the table) for reading the initial graph and writing out the final partitioning.

### C. Execution Times

Table VI (Right) shows the execution time in seconds for different GO configurations - GO-100, GO-75, GO-50, GO-25, and Mt-Metis. The execution times of GO-100 compare well with Mt-Metis and better for graphs with higher \(E/V\) ratio (PK, OK WK) with speedups ranging from 1.5× to 1.7×. (see Table IX). For the two larger graphs the results are quite different – for UK2002 the execution times for Mt-Metis are roughly 2× faster than GO-100 while for WK, Mt-Metis runs 1.6× slower. Nevertheless, GO-100 produces partitioning with fewer edgecuts than Mt-Metis for both UK2002 and WK.

The runtimes of GO scale with graph size ranging from few seconds for the smallest graph to roughly 32 minutes for large graphs. Let us compare the execution times of GO-100 with GO-25.

### D. GridGraph Performance vs. GO Partitioning

Next we study the impact of partitions produced on runtimes of graph algorithm on a state-of-the-art out-of-core system. We executed two graph algorithms, PageRank and WCC (Weakly Connected Components), on the GridGraph [25] out-of-core system using the partitions produced by GO-100, GO-75, GO-50 and GO-25. The execution times of GridGraph are given in Table X. As we can see from this table, the execution times of all the GO configurations are comparable. In fact, the runtimes are same for most of the GO configurations. In other words, reducing memory to 25% does not result in any slowdowns on GridGraph as the quality of partitions produced does not change significantly from GO-100 to GO-25. Therefore we can conclude that the quality of partitions produced by GO is fairly insensitive to the amount of memory provided to GO.

The above results are to be expected because, as we reduce memory to 25%, the number of edgecuts does not change significantly. Therefore we reduce the memory to 25%, as we reduce the memory available to GO, the number of edgetcuts does not change significantly.

In order to compare the effectiveness of GO’s partitioning with Mt-Metis partitioning and other simple partitioning schemes, we ran the workloads of PageRank and WCC on GridGraph. We compare the running times of GridGraph with GO-100, GO-75, GO-50, and GO-25.

on OK, WK and TW input graphs for multiple partitioning schemes. In addition to Mt-Metis and GO, we also collected the running times of GridGraph when using simple partitioning strategies, cyclic and block-cyclic, as these strategies have been used by existing out-of-core systems for evaluating graph queries to circumvent the memory intensive nature of graph partitioning. The results shown in Table XI demonstrate that running times for GO-100 partitioning are same or less than that for Mt-Metis, Cyclic and Block-Cyclic partitionings with the exception of WCC for k=8. Note that in Table XI the minimum execution times are shown in bold. This is to be expected because GO-100 always produces partitioning that is superior to the partitioning generated by other methods.

V. CONCLUSIONS

In this paper we presented the GO out-of-core graph partitioner that can function within the memory constraints imposed by the machine and successfully partition graphs that far exceed the size of a graph that can be held in memory. The execution time and memory requirements scale well with the graph size. For graphs that can be successfully partitioned using the in-memory Mt-Metis graph partitioner, GO produces high quality partitioning in terms of edgecuts and balance. In contrast to multilevel partitioning scheme used by Mt-Metis, GO is single level and it partitions the graph in two highly memory efficient parallel passes. For graphs that can be successfully partitioned by Mt-Metis on a single machine, GO produces balanced 8-way partitions with 11.8× to 76.2× fewer edgecuts using 1.9× to 8.3× lesser memory in comparable runtime.
